**Abstract:** AC pre-discharge currents, breakdown, and flashover voltage measurements are reported in a 10 mm needle-plane arrangement in a 4% Novec<sup>TM</sup> 4710/96% CO<sub>2</sub> gas mixture and compared with CO<sub>2</sub> for pressures up to 8.8 bar abs. Flashover measurements were performed on different solid dielectrics (Al<sub>2</sub>O<sub>3</sub>-filled epoxy resins, PTFE (Polytetrafluoroethylene) and PE (polyethylene)) for different roughness surface finishes. The effect of fixed conducting needles at various positions on electrical strength is reported. A strong nonlinear behaviour as function of gas pressure was observed for all the studied parameters (gas, needle position, solid insulator, insulator roughness). The non-linear behaviour is attributed to the inception and quenching of glow corona, in the interval between inception and breakdown or flashover voltages. It is found that a 4% concentration of Novec<sup>TM</sup> 4710 in CO<sub>2</sub> has a breakdown/flashover voltage  $\approx 1.14$  higher than CO<sub>2</sub>. The glow corona-induced stabilization effect is seen for pressures between 2 and 5 bar abs for all the studied parameters. The peak flashover voltage and its associated pressure of the different insulators are strongly dependent on surface roughness. At 8.8 bar abs, the flashover voltage level obtained with various materials was ordered as follows: PTFE > PE-UHMW > Epoxy > HDPE(High-density polyethylene).

## 1. Introduction

Novec<sup>TM</sup> 4710/CO<sub>2</sub> mixtures appear as those with a good compromise between equivalent insulation properties and the minimum operating temperature of apparatus while providing a significant reduction of the environmental impact. For a 4% Novec<sup>TM</sup> 4710/96% CO<sub>2</sub>, the equivalence with SF<sub>6</sub> at 5.5, 6.5, 7.5 bar abs are feasible for a minimum operating temperature of  $-30^{\circ}\text{C}$ ,  $-25^{\circ}\text{C}$ , and  $-20^{\circ}\text{C}$  [1–4], respectively. Novec<sup>TM</sup> 4710 (C<sub>4</sub>F<sub>7</sub>N)/CO<sub>2</sub> mixtures consist of complex molecules, formed from several basic elements (5 Carbons, 7 Fluorines, 2 Oxygens, and 1 Nitrogen), the energy absorption by the constituents of these mixtures causes their fragmentation into smaller radicals, that are more stable [5–7]. Once at rest, unlike SF<sub>6</sub>, the decomposition products do not recombine to the original chemical arrangement. They react with contaminants such as water [8], oxygen [9], the buffer gas, metal electrodes [10–12], solid dielectrics [13], and/or adsorbents [14] to form other chemically

stable decomposition by-products. High water content causes an increase in dielectric loss, accelerates the decomposition of Novec™ 4710 in the presence of electrical discharge or corona, and accelerates corrosion of the materials when in contact with decomposition products. For Novec™ 4710, limit values of moisture content are not yet set by the manufacturers. Under long-term operating conditions and with the effect of different combined constraints (electrical, thermal, impurities, etc.), the content of these products and new ones will increase.

The toxicity effect of most of these produced species is not known, and some of the species are undetectable via different characterization equipment (NMR-F ( $^{19}\text{F}$ ), Gas chromatography–mass spectrometry (GC-MS) and/or FTIR). Some are very toxic such as perfluoroisobutene  $\text{C}_4\text{F}_8$  (PFIB) or heptafluorobutyronitrile  $\text{C}_4\text{F}_7\text{N}$  (CAS number 375-00-8) and involve strict controls of their presence [15,16] (safety zone, venting, special personal protective equipment, gas detectors, and gas extraction). The respiratory system is the primary target of toxicity of inhaled pure Novec™ 4710 in humans, which was reported to cause cell mutagenicity and reprotoxic effects [17,18]. The available literature on carcinogenicity is incomplete.

In uniform electric fields, the surface electrical strength (ES) of Novec™ 4710/ $\text{CO}_2$  mixtures [19] relative to  $\text{CO}_2$  is lower than the volume electrical insulation strength [2,4] (see Figure 1). The validity of the optimal gas mixture must be extended and verified at different electric field distributions, on the surface and in the volume, particularly in highly divergent fields that appear when a metal particle is stuck at the insulator surface or very close to it [20].

**Figure 1.** Electrical strength (ES) relative to  $\text{CO}_2$  for different Novec™ 4710/ $\text{CO}_2$  gas mixtures in uniform electric field (Volume discharge [2,4] vs. Surface discharge (epoxy insulator) [19]).

In this study, the pre-discharge, volume, and surface discharge characteristics of a 4% Novec™ 4710/96%  $\text{CO}_2$  gas mixture and  $\text{CO}_2$  in a needle-plane electrode configuration are measured under different conditions of needle position, gas pressure, and insulator type (material, roughness).

## 2. Materials and Methods

The system consists of a high voltage AC source (50 kV rms, 3.75 kVA), a capacitive voltage divider (1:3750), an insulation defect model (protrusion), a detecting Current Transformer, a digital oscilloscope (Lecroy HDO6104), and a gas pressure chamber. The test rig is made of 316 L stainless steel with a volume of about 12 L, and Viton is used as the sealing material, with a maximum filling pressure up to 12 bar abs.

The insulation defect model consists of a needle (radius,  $R \sim 100 \mu\text{m}$ ) -plane electrode arrangement (see Figure 2). The tungsten needle is placed between two Bruce-shaped aluminium plane electrodes of 102 mm diameter and a flat area of 60 mm to provide a homogeneous background field. For each breakdown event, measurement series of 5 (solid flashover) and 10 (gas breakdown) individual discharges were performed, this allows to obtain useful values without rapidly degrading the state of

insulators and electrodes. The average of the measured values is taken as the flashover voltage  $V_{FO}$  or the breakdown voltage  $V_{BD}$ .

**Figure 2.** Electrode configuration: (a) Needle to a plane arrangement for breakdown investigations; (b) Insulator model for surface flashover experiments.

For breakdown measurements, an AC voltage ramp is increased at a rate of 2 kV/s up to 90% of the voltage level that initiates electrical discharges, and then 0.1 kV/s is used. Three minutes were kept in between the individual electrical discharges. The pressure limits for 4%Novec<sup>TM</sup> 4710 /96%CO<sub>2</sub> mixture are restricted by the test rig bushing flashover limit (58 kV peak, AC). The current activity was measured with a 500 MHz high frequency current transformer and a 1GHz Oscilloscope. The ramp method is employed to identify the inception voltage of partial discharge. The voltage is increased with the rate of 1 kV/s until the first pulse is detected.

Four insulator blocks are made of different solid dielectric materials: Polytetrafluoroethylene (PTFE), High-density polyethylene (HDPE), Ultra-high-molecular-weight polyethylene (UHMW-PE), and Al<sub>2</sub>O<sub>3</sub> filled epoxy resin, which are used in electrical equipment (See Figure 3). Surface roughness features are summarized in Table 1. Each insulator measured 13 mm in height and 30 mm in diameter. In order to simulate a particle at the triple junction point, a 3 mm needle with 0.1 mm in radius is fixed on the insulator surface and connected to the HV electrode with conductive aluminium tape. The effective gap between the needle tip and the ground electrode is 10 mm. A scanning electron microscopy (SEM), a Hitachi TM3030, equipped with an energy dispersive spectrometer (EDS) with a Quantax 75 EDS system is used.

### 3. Results

#### 3.1. Gas Breakdown

The gas breakdown characteristics in the highly divergent field are more complex in comparison with the uniform and slightly divergent electric field distributions, for CO<sub>2</sub> and 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> gas mixture. Figure 4 reports the AC V<sub>mean</sub> breakdown measurements, the positive and the negative inception voltages were measured at various pressures in the needle-plane configuration (gas gap) for a gap distance d = 10 mm: this corresponds to a field utilization factor of  $\eta = 0.0375$  calculated using equation (1). Where  $E_{max}$  is the maximum electric field computed using COMSOL Multiphysics<sup>®</sup> electrostatic field simulation.  $E_{average}$  stands for average electric field. The breakdown characteristic of CO<sub>2</sub> and 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> shows a strong nonlinear behaviour with the gas pressure increasing under AC voltage as opposed to the uniform field configuration that exhibits a linear trend [19]. This effect can be attributed to the space charge created in the gas volume. [21–24]. According to [21–24], the needle tip is covered with a cloud of charge carriers which will be stabilized by negative ions formed by attachment of electrons. Thus, the negative space charges generate a reduction of the electric field on the side of the tip. This causes an increase in the breakdown voltage. The experimental breakdown voltages measured for pressures up to 8.8 bar abs are strongly affected; the breakdown occurs under AC voltage on both positive and negative peaks. For a critical pressure, the positive half-cycle becomes decisive and the dielectric breakdown occurs at its peak value (see Table 2).

$$\eta = \frac{E_{average}}{E_{max}} \quad (1)$$

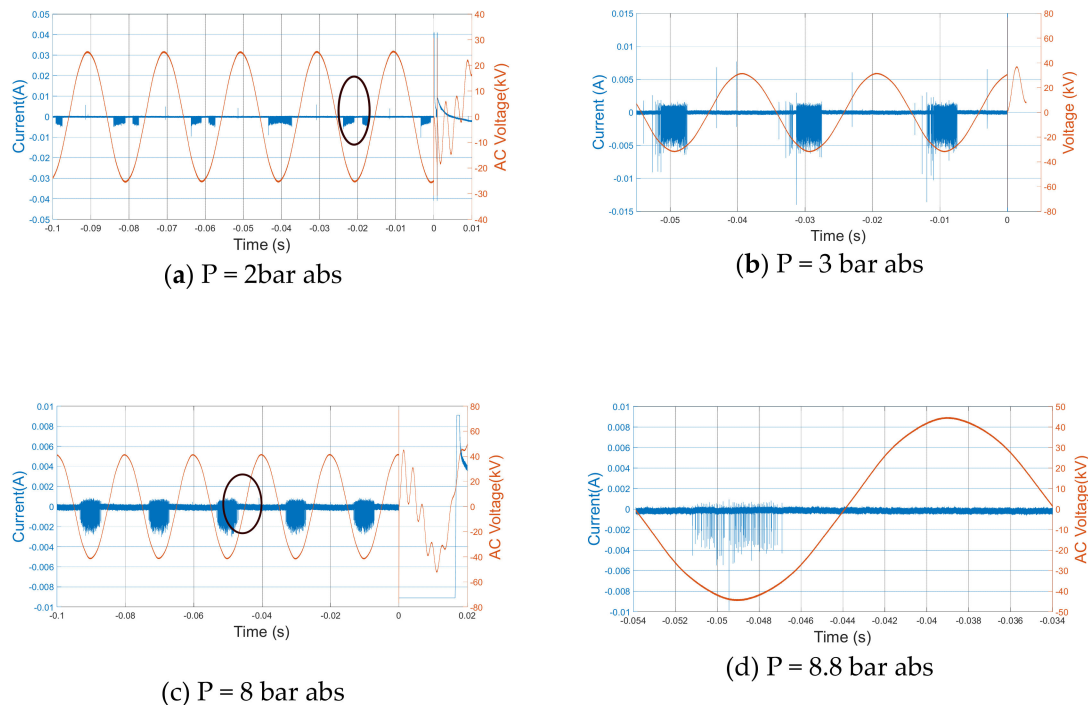

**Figure 4.** V<sub>mean</sub> Breakdown, positive and negative inception voltages as a function of gas pressure (CO<sub>2</sub>, needle on HV electrode).

**Table 2.** AC Breakdown polarity of CO<sub>2</sub> and 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> under different pressures up to 8.8 bar abs (Needle on HV Electrode).

| Needle on HV Electrode Polarity of Breakdown  |     |     |   |     |   |   |   |   |     |   |     |
|---|-----|-----|---|-----|---|---|---|---|-----|---|-----|
| Pressures (bar abs)                           | 0.4 | 1   | 2 | 2.5 | 3 | 4 | 5 | 6 | 7.2 | 8 | 8.8 |
| CO <sub>2</sub>                               | –   | –   | – | +   | + | + | + | + | +   | + | +   |
| 4%Novec <sup>TM</sup> 4710/96%CO <sub>2</sub> | –   | –/+ | + | +   | + | + | + | + | +   | + | +   |

For CO<sub>2</sub>, the positive and negative inception voltages increase linearly with the gas pressure increases as shown in Figure 4. The negative inception voltage is lower than the positive inception for the applied test pressures. For this electrode arrangement, a difference is observed between the inception voltage and the breakdown voltage. By increasing the pressure, the positive inception curve

and the breakdown voltage characteristics meet at a critical pressure ( $P_C$ ) 8bar abs. It can be seen from Table 2 that most of the breakdown happens during the AC positive half cycle. The voltage-current characteristic for different pressures is shown in Figure 5.

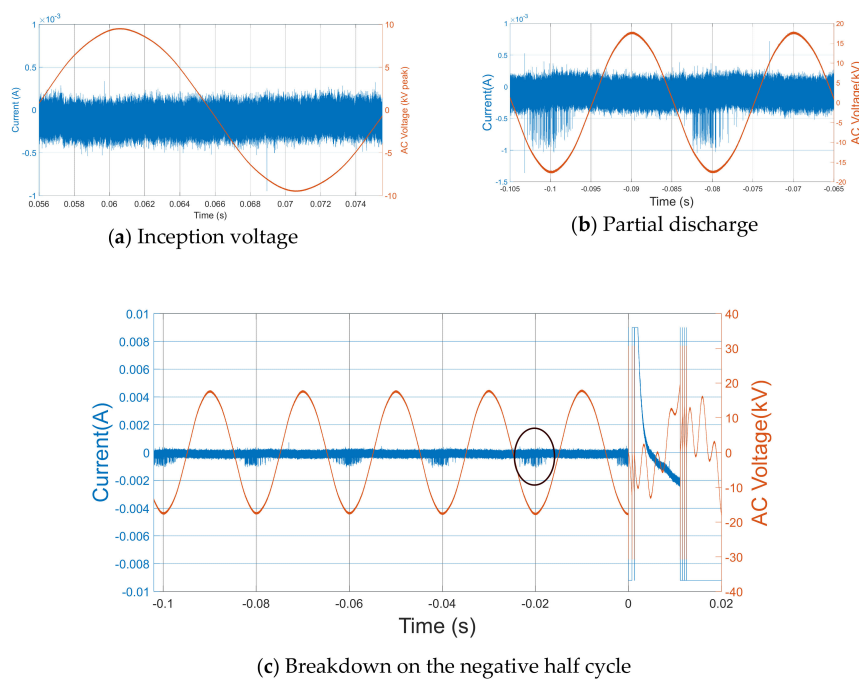

**Figure 5.** Voltage-current waveform for measuring partial discharge and breakdown voltages in  $\text{CO}_2$ .

Positive and negative breakdown, inception voltages of 4%Novec<sup>TM</sup> 4710/96% $\text{CO}_2$  are higher than those of  $\text{CO}_2$  for all test pressures. At 8.8 bar abs, the positive inception voltage of 4%Novec<sup>TM</sup> 4710/96% $\text{CO}_2$  is 1.18 higher than that of  $\text{CO}_2$  and 1.13 higher in the case of breakdown voltage. The positive inception voltage increases linearly as a function of pressure for pressures between 0.4 and 5 bar abs and shows a saturation trend above 5 bar abs as can be seen in Figure 6. The negative inception voltage is lower than for the positive polarity for pressures up to 2.5 bar abs, and above 2.5 bar abs, no negative current activities were detected, by increasing the pressure or the voltage up to breakdown. The positive inception curve and the breakdown curve are closest at a critical point  $P_C = 7.2$  bar abs. At this point, any increase of voltage causes a quick breakdown. The AC positive half cycle is decisive for disruptive discharge (see Table 2).

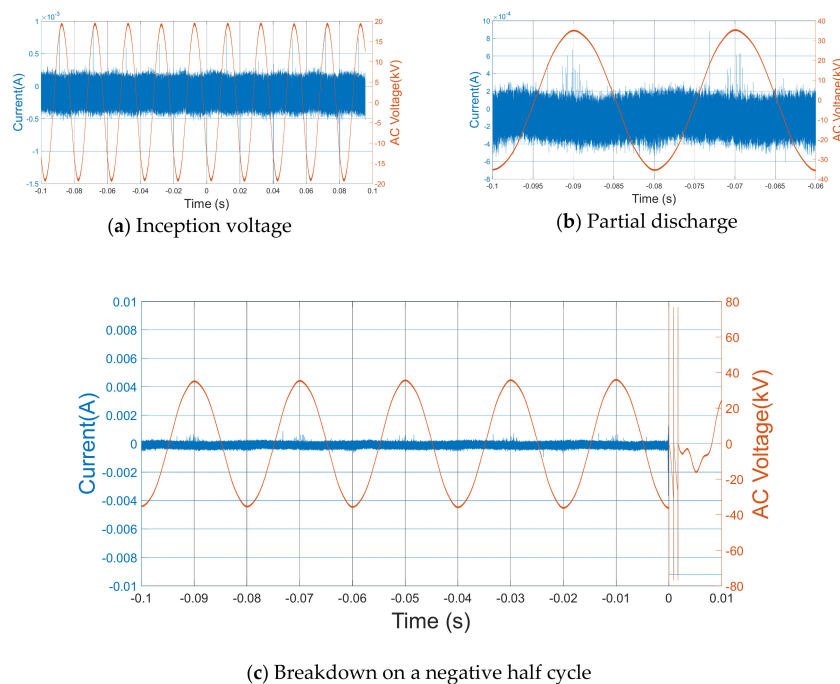

**Figure 6.**  $V_{\text{mean}}$  Breakdown, positive and negative inception voltages as a function of gas pressure (4%Novec<sup>TM</sup> 4710/96% $\text{CO}_2$ , needle on HV electrode).

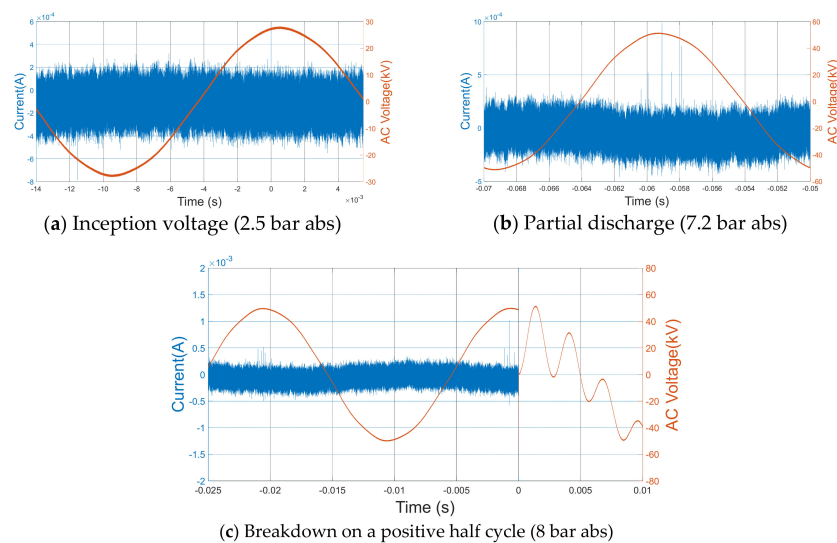

At 1 bar abs, breakdown polarity reversal occurs in 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> gas mixture. The voltage-current characteristics of 0.4 bar abs and 1 bar abs are shown in Figures 7 and 8 as follows. In CO<sub>2</sub>, the reversal polarity pressure is between 2 and 2.5 bar abs. The polarity reversal in this case is explained by a space charge attributed to the presence of CF<sub>3</sub>CFCN<sup>-</sup>, CFCN<sup>-</sup>, and CF<sub>3</sub><sup>+</sup> decomposed by C<sub>3</sub>F<sub>7</sub>CN (Novec<sup>TM</sup> 4710), distorted the electric field, which results in the difference of positive and negative breakdown voltage [25,26]. The voltage-current characteristic for different pressures is shown in Figure 9.

**Figure 7.** Voltage-current waveform for measuring inception voltage, partial discharge, and breakdown voltages (4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub>,  $P = 0.4$  bar abs).

**Figure 8.** Voltage-current waveform for measuring inception voltage, partial discharge, and breakdown voltages (4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub>,  $P = 1$  bar abs).

### 3.2. Discharge Characteristics with Solid Insulators in the Gap

Here, the measured AC  $V_{\text{mean}}$  flashover and negative inception voltages as a function of pressure are reported for the needle-plane configuration (solid–gas interface). The gap distance is  $d = 10$  mm, corresponding to a field utilization factor  $\eta = 0.025$  and the insulation material has a permittivity  $\epsilon_r = 2.1$ .

The flashover plots of CO<sub>2</sub> and 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> show a strong nonlinear behaviour as a function of gas pressure under AC voltage. The experimental flashover voltage measured for pressures up to 8.8 bar abs is strongly affected. The flashover occurs in AC voltage on both positive and negative peaks. For a critical pressure, the dielectric flashover occurs at the peak value of the positive half-cycle (see Table 3). The polarity reversal varies from an insulator to another depending on the gas nature.

**Table 3.** AC Flashover polarity under different pressures up to 8.8 bar abs (Needle on HV) Electrode).

(a) PE

For CO<sub>2</sub>, the negative inception voltage increases linearly as function of pressure, as shown in Figure 10. For this field distribution, a difference is observed between the inception voltage and the flashover voltage. By increasing the pressure, the negative inception curve and the flashover curve reach close voltage levels at a critical pressure,  $P_C = 8$  bar abs.

**Figure 10.**  $V_{\text{mean}}$  Flashover and Negative inception voltages as function of gas pressure ( $\text{CO}_2$ , PE-UHMW, Needle on HV electrode).

Figure 11 illustrates the instantaneous leakage current recorded during the surface discharge (corona/streamer) inception and the flashover (final jump). According to pre-flashover current measurements in Figure 11, different modes are involved in the nonlinear flashover voltage behaviour as function of the filling pressure.

(a)  $P = 2$  bar abs

(b)  $P = 3$  bar abs

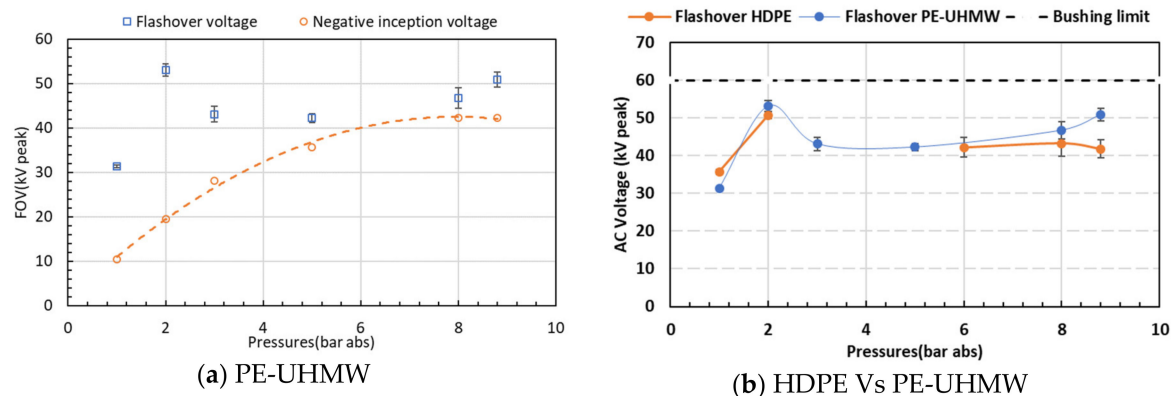

(c)  $P = 8$  bar abs (voltage 18.75 kV/div, current 5 mA/div)

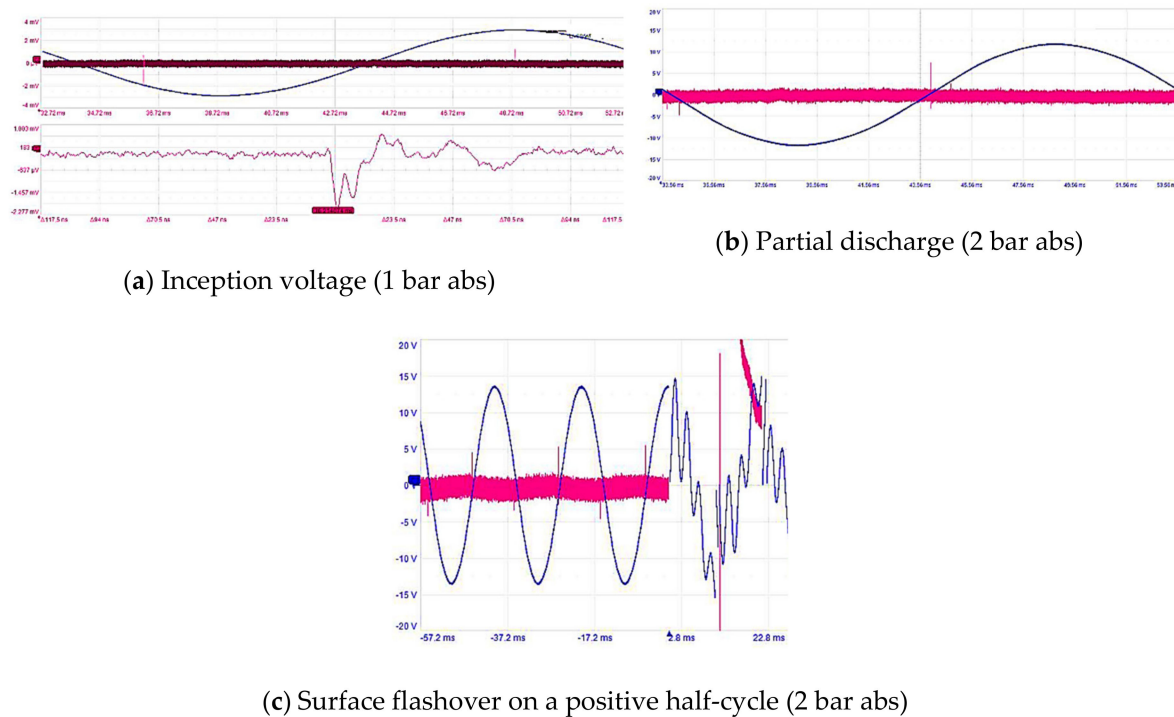

**Figure 11.** Voltage-current waveform for measuring partial discharge and surface flashover voltages ( $\text{CO}_2$ , PE-UHMW, Needle on HV electrode).

For 4%Novec<sup>TM</sup> 4710/96%  $\text{CO}_2$ , the flashover occurs on the positive half-cycle peak for all pressures (see Table 3b). The negative inception voltage increases linearly as function of pressure for pressures between 1 and 5 bar abs and shows a saturation trend above 5 bar abs which can be seen on Figure 12a. An example of an associated current of inception voltage at 1 bar abs is shown in Figure 13a. By increasing the pressure, the negative inception curve for various pressures and the flashover values

become closest at a critical pressure  $P_C = 6$  bar abs. The peak flashover voltage occurs at a pressure of 2 bar abs.

**Figure 12.**  $V_{\text{mean}}$  Flashover and negative inception voltages as function of gas pressure (4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub>, Needle on HV electrode).

**Figure 13.** Voltage-current waveform for measuring inception voltage, partial discharge and surface flashover voltages (4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub>, PE-UHMW, voltage 18.75 kV/div, current 1 mA/div).

Figure 12b shows the flashover voltage of HDPE Vs UHMW-PE insulators as function of pressure. For pressures of 2 to 6 bar abs, the flashover voltage of HDPE is higher than the test vessel's bushing withstands voltage limit. The UHMW-PE peak flashover voltage occurs at a pressure higher than that for UHMW-PE insulator. This peak pressure difference is attributed to the surface roughness of the insulators:  $R_a$  (UHMW-PE)  $\approx 18 \times R_a$  (HDPE), as can be seen in Table 1. For pressures,  $1 \leq P \leq 2$  bar abs and  $6 \leq P \leq 8$  bar abs, the associated flashover voltage values are equal. For  $P > 8$  bar abs, the HDPE flashover voltage decreases whereas, in PE- UHMW, some increase of flashover voltages occurs.

Figure 13 shows the instantaneous leakage current activity recorded of the discharge activity until the complete flashover of the insulator for a pressure of 2 bar abs. According to this figure, different modes of discharge are involved as previously for PE.

## (b) PTFE

For PTFE tests, it was observed that the flashover occurs on the positive half-cycle peak for the test pressure range (see Table 3b). The inception voltage increases linearly as a function of pressure as shown in Figure 14a, an example of an associated current of inception voltage at 1 bar abs is shown in Figure 15a. By increasing the pressure, the negative inception curve and the flashover values are closest at a critical point,  $P_C = 8$  bar abs. The peak flashover voltage occurs at a pressure between 2 and 5 bar abs.

**Figure 14.** Flashover voltage of the insulator defect (4%Novec™ 4710/96%CO<sub>2</sub>, PTFE, Needle on HV electrode).

(a) Inception voltage

(b) Surface flashover on the positive half cycle.

**Figure 15.** Voltage-current waveform for measuring surface discharges events (4%Novec™ 4710/96%CO<sub>2</sub>, PTFE, Needle on HV electrode, 1 bar abs).

The flashover voltages at 8.8 bar abs of N successive discharge events in the gas-solid interface are shown in Figure 14b–d. For 4%Novec™ 4710/96%CO<sub>2</sub> gas mixture, the results show that, in PTFE, significant variabilities always occur  $\sigma = \pm 10\% \mu$  (Gaussian Distribution), with a trend of improvement of flashover voltage as the discharges are repeated. Whereas in HDPE insulators, the values are more reproducible, the spread of the flashover voltage is smaller than for PTFE which is  $\sigma = \pm 5.25\% \mu$ . The mean flashover voltage with PTFE is 1.18 times higher than that with HDPE.

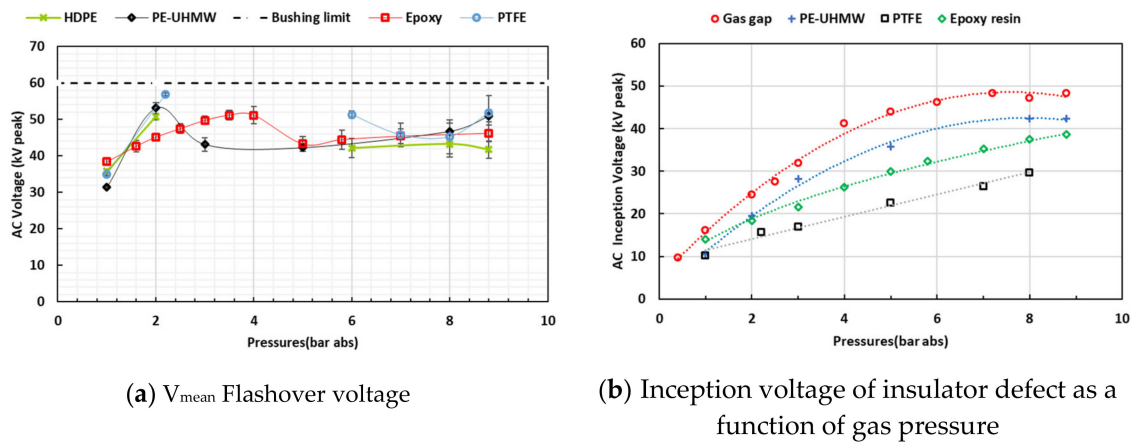

In Figure 14c, comparing 4%Novec™ 4710/96%CO<sub>2</sub> with CO<sub>2</sub> with the PTFE insulator, CO<sub>2</sub> exhibits a smaller spread  $\sigma = \pm 3\% \mu$  and the values are more reproducible. The mean flashover voltage of 4%Novec™ 4710/96%CO<sub>2</sub> is 1.25 times higher than that obtained with CO<sub>2</sub>.

In Figure 14d, comparing the effect of the needle position on flashover voltage, the needle on the ground electrode presents lower variability and more reproducible flashover values  $\sigma = \pm 3.3\% \mu$ . The mean flashover voltages are identical for Needle on HV electrode and needle on ground electrode configurations.

### (c) Epoxy

The flashover occurs on the negative half-cycle peak for pressures between 1 and 4 bar abs and on the positive half cycle above 4 bar abs for both roughness values of  $R_a = 0.5 \mu\text{m}$  and  $5 \mu\text{m}$  (see Table 3b). Compared with PE and PTFE, the epoxy flashover has different peak pressure values and similar flashover voltages for pressures between 5 and 8.8 bar abs (see Figure 16a). At 8.8 bar abs, the comparison of flashover voltage is as follows:

$$V_{\text{Flashover}} (\text{PTFE}) > V_{\text{Flashover}} (\text{PE} - \text{UHMW}) > V_{\text{Flashover}} (\text{Epoxy}) > V_{\text{Flashover}} (\text{HDPE}) \quad (2)$$

**Figure 16.** (4%Novec™ 4710/96%CO<sub>2</sub>, HDPE Vs PE-UHMW Vs Epoxy 2 ( $R_a = 5 \mu\text{m}$ ) Vs PTFE, Needle on HV electrode).

For pressures between 1 and 4 bar abs, the peak flashover voltage and its associated pressure for different insulators are strongly dependent on the surface roughness  $R_a$ , Increasing  $R_a$  causes a peak pressure increase and a decrease of its associated flashover voltage. The comparison of roughness of insulators is as follow (see Table 1):

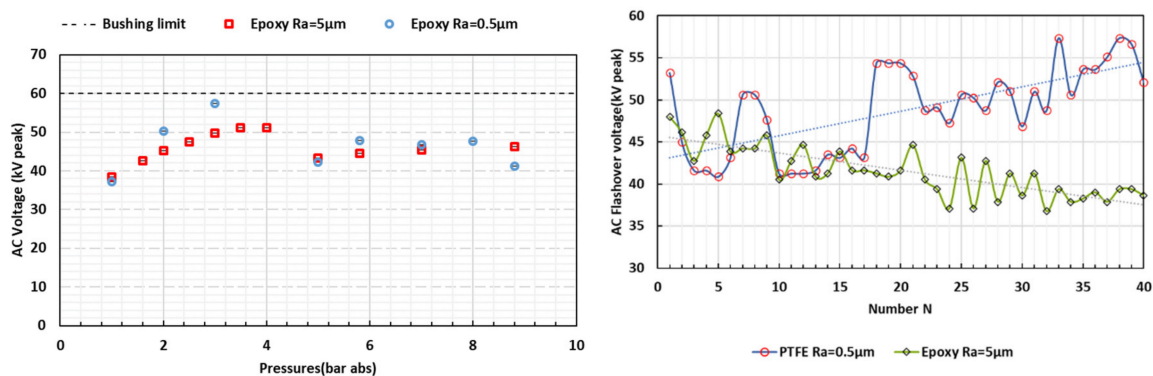

$$R_a (\text{Epoxy}) > R_a (\text{PE} - \text{UHMW}) > R_a (\text{PTFE}) > R_a (\text{HDPE}) \quad (3)$$

The inception voltage with the different insulators compared to those obtained with the gas gap values is shown in Figure 16b. The comparison of inception voltage is as follows:

$$V_{\text{Inception}} (\text{Gas gap}) > V_{\text{Inception}} (\text{PE} - \text{UHMW}) > V_{\text{Inception}} (\text{Epoxy}) > V_{\text{Inception}} (\text{PTFE}) \quad (4)$$

During the first step of flashover, the permittivity affects the inception voltage. According to [27], when a solid insulator is close or in contact with a metallic electrode, the electrical field lines are deviated and directed to the solid insulator and increasing also the electrical gradient near the HV electrode in comparison with the same gap without a solid insulator. The permittivity of the solid insulator increases the electrical gradient that causes a local ionization enough to incept partial discharges. For comparison, the field utilization factors for the electrode arrangement are  $\eta_1 = 0.025$  (PTFE,  $\epsilon_r = 2.1$ ) and  $\eta_2 = 0.0375$  (gas gap,  $\epsilon_r \approx 1$ ).

Epoxy resin was assessed for different values of surface roughness  $R_a$  and the results are shown in Figure 17a. For pressures between 5 and 8.8 bar abs, the flashover voltages are similar and present a saturation trend for Epoxy 1 ( $R_a = 0.5 \mu\text{m}$ ) and Epoxy 2 ( $R_a = 5 \mu\text{m}$ ). The increase of roughness  $R_a$  reduces the amplitude of voltage peak at 4 bar abs. Glow corona stabilization is stronger when decreasing  $R_a$  (see Figure 17a).

(a) Epoxy insulators:  $R_a = 0.5 \mu\text{m}$  Vs  $R_a = 5 \mu\text{m}$  (b) PTFE Vs Epoxy 2 ( $R_a = 5 \mu\text{m}$ ),  $P = 8.8$  bar abs

(c) (PTFE, Epoxy) Vs N<sub>2</sub> (Epoxy),  $P = 8.8$  bar abs

**Figure 17.** Flashover voltage of insulator defect as function of gas pressure (4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub>, Needle on HV electrode).

In Figure 17b and for 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> gas mixture, the results show that, in Epoxy ( $R_a = 5 \mu\text{m}$ ), significant variabilities in measured values always occurs  $\sigma = \pm 7.27\% \mu$  (Gaussian Distribution), with a trend of reduction of flashover voltage as the breakdown events were repeated. Whereas in HDPE insulators, for  $N = 40$ , the flashover voltage of PTFE is 1.35 times higher that obtained with

Epoxy ( $R_a = 5 \mu\text{m}$ ). For the first flashover event ( $N = 1$ ), the flashover voltage of PTFE is 1.10 times higher compared with that obtained with Epoxy ( $R_a = 5 \mu\text{m}$ ).

In Figure 17c and for  $N_2$ , the results show that in Epoxy ( $R_a = 5 \mu\text{m}$ ), significant spread is always measured  $\sigma = \pm 9.13\%$ . A flashover voltage reduction occurs, caused by surface degradation. For the first flashover event ( $N = 1$ ), the flashover voltage of 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> (Epoxy,  $R_a = 5 \mu\text{m}$ ) is 1.14 times higher compared with that of  $N_2$  (Epoxy,  $R_a = 0.5 \mu\text{m}$ ).

### 3.3. Discharge Characteristics for an Earthed Needle

The breakdown plot of 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> gas mixture shows similar behaviour and similar discharge patterns with the needle position (HV vs ground electrode) under AC voltage (see Figure 18a). The non-linear breakdown behaviour is attributed to the inception of a corona glow discharge, detected in the same range of pressure for both needle positions (see Figures 19b and 20a). The breakdown occurs in AC voltage on both positive and negative half cycle peaks. Tables 2 and 4a indicate a complementarity of breakdown polarities when changing the position of the needle. The plot shows different peak pressure values as a function of needle location. The inception voltage for the needle at the ground electrode (NOGNDE) is lower compared to the needle at the HV electrode (NOHVE) position for all pressures.

(a)  $V_{\text{mean}}$  Breakdown and positive inception voltages of 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub>

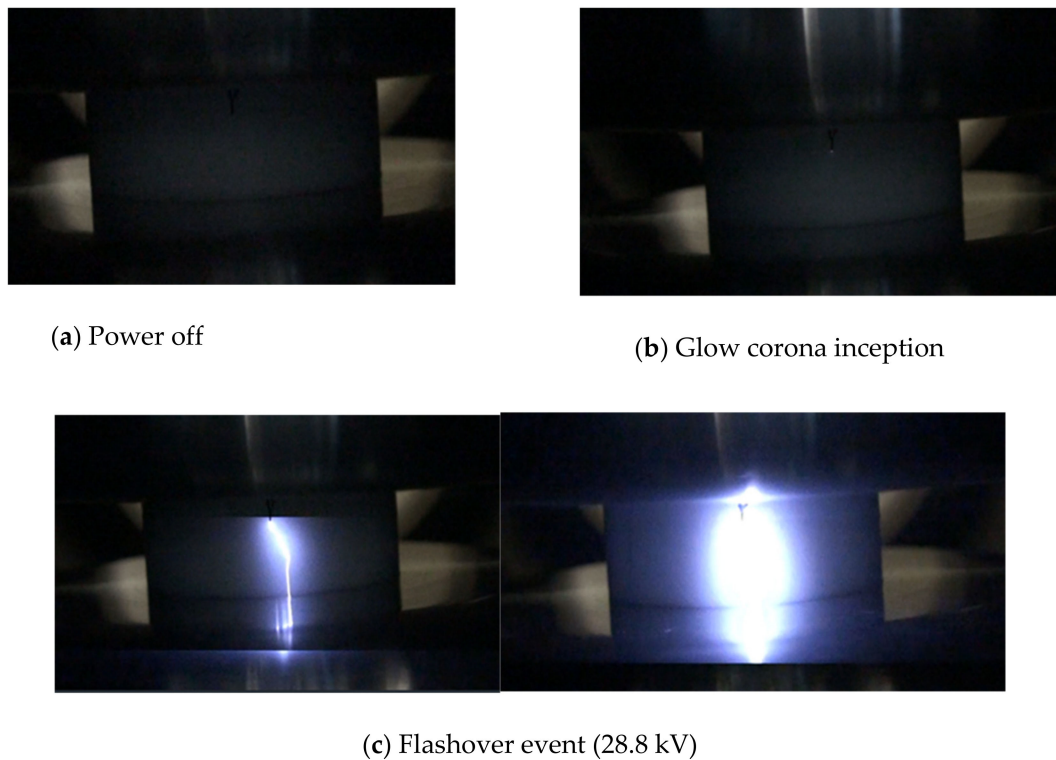

(b)  $V_{\text{mean}}$  Flashover voltage of CO<sub>2</sub>

(c)  $V_{\text{mean}}$  Flashover voltage of 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub>, PTFE

**Figure 18.** Breakdown/Flashover voltages as function of gas pressure (Needle on HV electrode NOHVE Vs Needle on ground electrode NOGHDE).

**Figure 19.** AC (kV peak) flashover voltage for CO<sub>2</sub> (PTFE at 2 bar abs) as a function of applied voltage.

**Figure 20.** Positive glow corona onset: for 4%Novec<sup>TM</sup> 4710/96% CO<sub>2</sub> for an applied voltage.

The flashover plot of 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> or CO<sub>2</sub> shows similar voltage levels for both needle positions (HV vs ground electrode, with PTFE) under AC voltage, and for pressures outside the [2, 5 bar abs] range (see Figure 18b,c).

As can be seen from Figure 17, the breakdown voltage of 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> gas mixture is higher compared to the flashover voltage in the pressure range. While 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> flashover voltages is higher than CO<sub>2</sub> for both needle positions, at 8.8 bar abs, electrical strength (4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub>) = 1.19 times the electrical strength of CO<sub>2</sub>.

The flashover occurs under AC voltage at both positive and negative half cycle peaks. Table 3a,b and Table 4b,c show a complementarity of flashover polarities when changing the position of the needle. Figure 18b,c show different peak pressure values as function of needle position, for 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> or CO<sub>2</sub>.

## 4. Discussion

### 4.1. Discharge Characteristics of Gases

#### 4.1.1. CO<sub>2</sub>

According to the pre-breakdown current measurements shown in Figure 5, two modes have been identified in the nonlinear breakdown voltage behaviour as a function of the filling pressure:

$0.4 < P \leq 2$  bar abs: The breakdown is led by streamer, corona glow and leader discharges [28,29]. The breakdown occurs at the negative half-cycle peak (see Figure 5a). On the positive half cycle: at  $P = 2$  bar abs, the onset of positive corona glow was detected (see Table 5b), but did not develop to full breakdown, because of the shielding effect produced by the positive corona glow.

**Table 5.** Glow Corona onset as a function of pressure in.

| <b>(a) 4%Novec<sup>TM</sup> 4710/96%CO<sub>2</sub> (UHMW-PE, Flashover Discharge)</b> |   |   |   |   |   |     |
|---|---|---|---|---|---|-----|
| Pressure (bar abs)  | 1 | 2 | 3 | 5 | 8 | 8.8 |
| 4%Novec <sup>TM</sup> 4710/CO <sub>2</sub> (UHMW-PE)                                  |   | × | × | × |   |     |
| <b>(b) CO<sub>2</sub> (Breakdown Discharge)</b>                                       |   |   |   |   |   |     |
| Pressure (bar abs)  | 1 | 2 | 3 | 5 | 8 | 8.8 |
| CO <sub>2</sub>   |   | × | × | × |   |     |
| <b>(c) CO<sub>2</sub> (UHMW-PE, Flashover Discharge)</b>                              |   |   |   |   |   |     |
| Pressure (bar abs)  | 1 | 2 | 3 | 5 | 8 | 8.8 |
| CO <sub>2</sub> (UHMW-PE)   |   | × | × | × |   |     |

$P > 2$  bar abs: The breakdown polarity reversal is explained as follows: in the negative needle electrode, corona discharge is created near the needle tip, as shown in Figure 5b–d in the negative pre-breakdown current waveform. A positive space charge is left at the needle tip and results in a significant increase of the electric field near the needle tip. Near the anode (plane electrode), the negative space charge causes an increase of the electric field. The positive and negative space charge results in a more uniform field distribution in the main part of the gap. This increases the breakdown voltage.

When the breakdown occurs on the positive half-cycle peak; it is seen that positive glow corona appeared for pressures up to 5 bar abs. In fact, the space charge near the needle tip results in a reduced electric field. The electrode is virtually elongated, the gap width is reduced, and the electric field is enhanced in the remaining gap, resulting in a reduction in breakdown voltage.

$$V_{BD} \text{ (positive half cycle)} < V_{BD} \text{ (negative half cycle)} \quad (5)$$

#### 4.1.2. 4%Novec™ 4710/96% CO<sub>2</sub>

$0.4 < P \leq 1$  bar abs: inception voltages are detectable on both polarities. When the breakdown occurs on a negative half-cycle peak, no positive glow corona discharge is detectable in this range of pressure. The gaseous breakdown is led by negative streamer discharges, explained as follow:

- (i) Primary electrons are emitted from the cathode (needle electrode), the first avalanche develops toward a decreasing field (See Figures 7a and 8a), then
- (ii) The first avalanche reaches its critical size and, with increasing applied voltage, new avalanches are initiated (See Figure 7b), and finally
- (iii) Increasing the voltage induces more current activity, which generates a sufficient critical space charge avalanche to create a discharge (See Figure 7c).

$P \geq 1$  bar abs: Increasing the pressure initiates the dequenching of negative current activity to complete extinction for pressures between 2.5 and 8.8 bar abs (see Figure 9b,c). Partial discharge is represented exclusively in multiple pulses around the positive half cycle peak (see Figure 8b). In CO<sub>2</sub> and for high pressures (8 bar abs), only one single positive pulse was recorded prior to breakdown (see Figure 5c), the streamer channels (centered with positive half cycle peak) transit to leader channels and arrive at the grounded electrode immediately.

#### 4.2. Surface Discharge and Flashover with Solid Insulator

The flashover voltage is lower than the breakdown voltage of 4%Novec™ 4710/96% CO<sub>2</sub> gas mixture and CO<sub>2</sub>, for the same electrode configuration and gap. As the voltage increases, partial discharge appears at the interface between the HV electrode and the solid insulator. With the increase of the applied voltage, the discharge activity is more intense and the leader propagates along the insulator surface until a full ground electrode -flashover- (see Figure 19) as observed by [30].

The behavior of surface discharges on an insulator and their flashover has similarities with partial discharges and breakdown of the gas when no insulators are present, and this is dependent on the gas nature, the gas pressure filling and the type of solid insulator. On the other hand, the surface discharge current is greater than for the gas alone pre-breakdown for the same configuration (gas, electrodes configuration and gap distance), but the current discharge are less frequent. This observation makes it possible to highlight the effective charge injection from the solid insulator along the discharge propagation as suggested by many researchers [31]. Indeed, photoemission and electrical field emission from the solid insulator are possible supplementary charge injection mechanisms that can explain the current pulse increase. The electrical field emission is usually governed by the intensity of the tangential electrical gradient at the insulator surface [31]. For the photoemission, the mechanism is more complex; as the photoemission of the solid dielectric usually needs less energy than the photoionization of the gas [32]. The extraction of the electrons from the solid insulator leaves a positive charge at the surface that interacts with the discharge head, and generates:

- (i) A repulsion effect in the case of positive space charge at the head that pushes the discharge to move away in order to catch other photoelectrons (photoionization and photoemission). Those photoelectrons are responsible for the positive current pulses and the heating of the leader/spark channel.
- (ii) An attraction effect of negative space charge from the solid insulator and from the gas that contribute to the increase of the local attachment and/or recombination at the interface. This can explain the presence of electronegative elements at the arced insulator surface.

The heating of the leader channel interacts also with the insulator surface, and may generate supplementary electrons by a thermo-emission effect which, in turn contributes to the creation of a preferential path across the surface.

The polarity of flashover depends on the gas and insulator type, as presented in Tables 3 and 4. The polarity of flashover for all used insulators is identical to breakdown in gas gap alone independent

of the gas type, except for the Epoxy insulator. Based on this observation, it can be said that the gas pressure plays an important role on the discharge propagation causing the discharge to stick to the insulator surface as the pressure increases as observed by [33,34]. It was found that, depending on the polarity, the efficiency of the charge injection from the solid insulator or the attachment/recombination process will govern the propagation path. The attachment and recombination processes mainly occur at the solid/gas interface. Indeed, the results of the analysis with SEM-EDS of arced and no-arc PTFE samples show an increase of Fluorine at the arced insulator surface with 4%Novec™ 4710/CO<sub>2</sub> gas mixture. In the case of Epoxy, the SEM-EDS results show an increase of Oxygen, Bromine, Aluminium and Fluorine at the arced insulator surface tested with 4%Novec™ 4710/CO<sub>2</sub> gas mixture.

According to Figure 11, and based on the previous explanations, the description of the surface discharge inception and propagation can be clarified too, depending on the gas pressure and type of insulator:

#### 4.2.1. CO<sub>2</sub>

- (i)  $1 < P \leq 2$  bar abs: The flashover occurs on the negative half-cycle peak (see Table 3a) where the negative leader current pulses are observed at the beginning of the negative half-cycle. The leader current pulses are the result of charge accumulation left by the previous activity. During the positive half-cycle, the density of the current pulses is less than is typical for positive streamers and presents also some leader current peaks after charge injection at the beginning of the positive half-cycle. The negative half-cycle just before flashover shows that the leader propagates quickly (final jump) because, at this stage, the critical length was achieved and the unbridged gap between the discharge head and the ground electrode is partially ionized, as suggested in [35,36].
- (ii)  $P > 2$  bar abs: The flashover occurs on the positive half-cycle peak where positive streamers currents and leader pulse current are observable for pressures up to 5 bar abs (see Table 3c). During the positive half cycle, at  $P = 3$  bar abs and as the voltage increases, the stages to discharges are streamer onset, glow corona onset and the leader channels bypass the positive glow corona volume and follows the same process as described in (i). Whereas, during the negative half cycle, the streamer mode is involved before the flashover on the positive half-cycle (See Figure 11b).
- (iii) For pressures  $P \geq P_c$ , the gas breakdown (see Figure 5c in) and the surface flashover (see Figure 11c) occur on the positive half-cycle peak. In Figure 5c, the transition from streamer discharge to leader discharge is immediate and breakdown is immediately after streamer onset, with only a small increase of voltage. Comparing the current activities in Figures 5c and 11c (negative half-cycles), the surface pre-discharge peak current is 4 times higher than the gas pre-discharge one. In fact, the surface pre-discharge includes supplementary mechanisms for discharge development (photoemission, photoionization and electron detachment). Furthermore, no current pulses were detected preceding surface flashover as shown in Figure 11c. Ions generated during the pre-discharge phenomenon on negative half-cycles may not be removed before polarity reversal occurs, resulting in a space-charge induced field distortion. This results in a reduction of the surface flashover voltage. On the other hand, it was observed that the surface discharge tends to stick the insulator surface with the increasing of the gas pressure [33,34,37,38]. This can explain the relative stability of the surface flashover voltage for high pressures: the main electrical charges are collected from insulator caused by the increase of the attachment process with the gas pressure rising. Moreover, according to [35–37], the discharge velocity increases with the energy increase according to the following equation.

$$v_d(t) = \sqrt[3]{\frac{2\beta P(t)}{M_v \pi a_d^2}} \quad (6)$$

$\beta$  is the energy fraction used for the discharge propagation and varies between 0 and 1,  $P(t)$  is the discharge power during a lap time  $dt$ ,  $a_d$  is the discharge radius and  $M_v$  is the gas molecular volume.

The more is energy injected or applied, the more the discharge is faster. For higher pressures, the inception voltage is higher resulting in a higher velocity of electrons and ions. Resulting in a faster avalanche growth and faster discharge development, and the corona initiation curve and the flashover curve reach closer voltage levels.

#### 4.2.2. 4%Novec™ 4710/96% CO<sub>2</sub>

Steady glow corona discharge occurs at 2 bar abs (see Table 5a), the associated currents were shown in Figure 13b,c the glow discharge is present until flashover. At 3 bar abs, glow discharge is detected. The discharge switches on and off at a voltage well below the flashover voltage. With increasing voltage, the glow discharge is extinguished up to flashover.

At 1 bar abs, inception discharges are detectable for both polarities. The flashover occurs on the positive half-cycle peak. No glow corona discharge is detected, and the surface flashover is led by a positive streamer discharges, as explained in the steps below.

The first avalanche reaches its critical size and with increasing applied voltage, new avalanches are created (See Figure 15b, positive half cycle).

Increasing the voltage generates higher current activity and a sufficient critical space charge avalanche to initiate a discharge (See Figure 15b, positive half cycle).

The breakdown/flashover characteristics of 4%Novec™ 4710/96% CO<sub>2</sub> and CO<sub>2</sub> as function of pressure under non-uniform electric field distribution are strongly nonlinear. Associated pre-discharge activities were determined (inception voltage, positive and negative streamer activities). The non-linear behaviour is attributed to the inception and quenching of positive glow corona, in the interval between inception and breakdown voltages (see Figure 20). Table 5 summarizes the glow corona inception voltages as a function of pressure for the gaseous gap with solid-gas interface.

For epoxy and for 4%Novec™ 4710/96% CO<sub>2</sub> gas mixture, the pressure at which polarity reversal occurs is higher than that obtained with PTFE and PE (see Table 3b). The adsorption effect of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (Alumina, aluminium (III) oxide) on decomposed C<sub>4</sub>F<sub>7</sub>N/N<sub>2</sub> was proven [13]. The  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> has a strong adsorption effect on the main insulating medium C<sub>3</sub>F<sub>7</sub>CN, and can be explained by the fact that the average pore diameter of the  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> adsorbent is 0.9 nm, and the average diameter of the macropores are 1~2 nm, i.e., larger than the dynamic diameter of the C<sub>3</sub>F<sub>7</sub>CN and its post-discharge decomposition products (between 0.48 and 0.77 nm).

## 5. Conclusions

The breakdown characteristic of 4%Novec™ 4710/96% CO<sub>2</sub> and CO<sub>2</sub> as a function of pressure under non-uniform electric field distribution is strongly nonlinear. The non-linear behaviour is attributed to the inception and quenching of positive glow corona, in the interval between inception and breakdown voltages. Breakdown, positive, and negative discharge inception voltages of 4%Novec™ 4710/96% CO<sub>2</sub> are higher than those of CO<sub>2</sub> for all test pressures used here. At 8.8 bar abs, the positive inception voltage of 4%Novec™ 4710/96% CO<sub>2</sub> is 1.18 highest relative to CO<sub>2</sub> and 1.13 higher for the breakdown voltage.

Compared with PE and PTFE, the epoxy flashover has different peak pressure values and similar flashover voltages for pressures between 5 and 8.8 bar abs. At 8.8 bar abs, the comparison of flashover voltage is as follows:

$$V_{\text{Flashover}}(\text{PTFE}) > V_{\text{Flashover}}(\text{PE-UHMW}) > V_{\text{Flashover}}(\text{Epoxy}) > V_{\text{Flashover}}(\text{HDPE}) \quad (7)$$

The comparison of inception voltage of the different insulators is as follows:

$$V_{\text{Inception}}(\text{Gas gap}) > V_{\text{Inception}}(\text{PE-UHMW}) > V_{\text{Inception}}(\text{Epoxy}) > V_{\text{Inception}}(\text{PTFE}) \quad (8)$$

For 4%Novec<sup>TM</sup> 4710/96% CO<sub>2</sub> gas mixture, the results show that in Epoxy (Ra = 5 µm), significant scatter always occurs  $\sigma = \pm 7.27\%$  µ (Gaussian Distribution), with a trend of reduced flashover voltage as the discharges repeated. In contrast, with HDPE insulators and for N = 40, the flashover voltage of PTFE is 1.35 times higher compared with Epoxy (Ra = 5 µm).

For 4%Novec<sup>TM</sup> 4710/96% CO<sub>2</sub> gas mixture, the results show that in PTFE, significant scatter always occurs  $\sigma = \pm 10\%$  µ (Gaussian Distribution), with a trend of increasing of flashover voltage as the discharges repeated. In contrast, with HDPE insulators, the values are more reproducible, and the scatter of the flashover voltage is smaller than that with PTFE  $\sigma = \pm 5.25\%$  µ. The mean flashover voltage of PTFE is 1.18 times higher compared with HDPE.

The breakdown or flashover voltages of 4%Novec<sup>TM</sup> 4710/96% CO<sub>2</sub> gas mixture show symmetrical behaviour and similar discharge voltages as function of needle position (at HV or at ground electrode) under AC voltage. The surface flashover voltage is lower than the discharge voltage of 4%Novec<sup>TM</sup> 4710/96% CO<sub>2</sub> gas mixture and CO<sub>2</sub> without the insulator. For a critical pressure, the dielectric flashover/breakdown occurs at the positive half-cycle peak instant. The change in polarity at which the discharge occurs varies from one insulator to another, depending on the gas type.

The peak flashover voltage and its associated pressure for the different insulators are strongly dependent on surface roughness Ra. The increase of roughness Ra reduces the amplitude of voltage peak. Glow corona stabilization is stronger when the roughness Ra is decreased.
